AN EFFICIENT PROCEDURE TO DOUBLE AND ADD POINTS ON AN ELLIPTIC CURVE

KIRSTEN EISENTRÄGER, KRISTIN LAUTER, AND PETER L. MONTGOMERY

Abstract. We present an algorithm that speeds exponentiation on a general elliptic curve by an estimated 3.8% to 8.5% over the best known general exponentiation methods when using affine coordinates. This is achieved by eliminating a field multiplication when we compute $2P + Q$ from given points P, Q on the curve. We give applications to simultaneous multiple exponentiation and to the Elliptic Curve Method of factorization. We show how this improvement together with another idea can speed the computation of the Weil and Tate pairings by up to 7.8%.

Keywords: elliptic curve cryptosystem, elliptic curve arithmetic, exponentiation, ECM, pairing-based cryptosystem.

1. Introduction

This paper presents an algorithm which can speed exponentiation on a general elliptic curve, by doing some arithmetic differently. Exponentiation on elliptic curves is used by cryptosystems and signature schemes based on elliptic curves. Our algorithm saves an estimated 3.8% to 8.5% of the time to perform an exponentiation on a general elliptic curve, when compared to the best-known general methods. This savings is important because the ratio of security level to computation time and power required by a system is an important factor when determining whether a system will be used in a particular context.

Our main achievement is that we can eliminate a field multiplication whenever we are given two points P, Q on an elliptic curve and need $2P+Q$ (or $2P-Q$) but not the intermediate results $2P$ and $P+Q$. This sequence of operations is needed many times when, for example, left-to-right binary exponentiation is used with a fixed or sliding window size.

Some algorithms for simultaneous multiple exponentiation alternate doubling and addition steps, such as when computing $k_1P_1 + k_2P_2 + k_3P_3$ from given points P_1, P_2, and P_3. Such algorithms can use our improvement directly. We give applications of our technique to the Elliptic Curve Method for factoring and to speeding the evaluation of the Weil and Tate Pairings.

The paper is organized as follows. Section 2 gives some background on elliptic curves. Section 3 gives a detailed version of our algorithm. Section 4

Date: August 5, 2002.

estimates our savings compared to ordinary left-to-right exponentiation with windowing. Section 5 illustrates the improvement achieved with an example. It also describes applications to simultaneous multiple exponentiation and the Elliptic Curve Method for factoring. Section 6 adapts our technique to the Weil and Tate pairing algorithms. Section 7 gives the pseudocode for implementing the improvement, including abnormal cases.

2. Background

Elliptic curves are used for several kinds of cryptosystems including key exchange protocols and digital signature algorithms (see for example [IEEE]). If q is a prime or prime power, we let $\mathbb{F}_q$ denote the field with q elements. When $\gcd(q,\ 6) = 1$, an elliptic curve over the field $\mathbb{F}_q$ is given by an equation of the form

$$E_{\text{simple}}:\ y^2 = x^3 + ax + b$$

with $a,\ b$ in $\mathbb{F}_q$ and $4a^3 + 27b^2 \neq 0$. (See [Silverman, p. 48]).

A more general curve equation, valid over a field of any characteristic, is considered in section 7. That case subsumes the equation

$$E_2:\ y^2 + xy = x^3 + ax^2 + b$$

with $a,\ b$ in $\mathbb{F}_q$ and $b \neq 0$, which is sometimes used when the field has characteristic 2.

In all cases the group used when implementing the cryptosystem is the group of points on the curve over $\mathbb{F}_q$. If represented in affine coordinates, the points have the form: $(x,\ y)$, where x and y are in $\mathbb{F}_q$ and they satisfy the equation of the curve, plus a distinguished point $\mathbf{O}$ (called the *point at infinity*) which acts as the identity for the group law. Throughout this paper we work with affine coordinates for the points on the curve.

Points are added using a geometric group law which can be expressed algebraically through rational functions involving x and y. Whenever two points are added, forming $P + Q$, or a point is doubled, forming $2P$, these formulae are evaluated at the cost of some number of multiplications, squarings, and divisions in the field. For example, using E_{simple}, to double a point in affine coordinates costs 1 multiplication, 2 squarings, and 1 division in the field, not counting multiplication by 2 or 3 [BSS, p. 58]. To add two *distinct* points in affine coordinates costs 1 multiplication, 1 squaring, and 1 division in the field. Performing a doubling and an addition $2P + Q$ costs 2 multiplications, 3 squarings and 2 divisions if the points are added as $(P + P) + Q$, i.e., first double P and then add Q.

3. The Algorithm

Our algorithm performs a doubling and an addition, $2P+Q$, on an elliptic curve E_{simple} using only 1 multiplication, 2 squarings, and 2 divisions (plus an extra squaring when $P = Q$). This is achieved as follows: to form $2P+Q$, where $P = (x_1,\ y_1)$ and $Q = (x_2,\ y_2)$, we first find $(P+Q)$, except we omit

its y-coordinate, because we will not need that for the next stage. This saves a field multiplication. Next we form $(P + Q) + P$. So we have done two point additions and saved one multiplication. This trick also works when $P = Q$, i.e., when tripling a point. One additional squaring is saved when $P \neq Q$ because then the order of our operations avoids a point doubling.

Elliptic curve cryptosystems require multiplying a point P by a large exponent k. If we write k in binary form and compute kP using the left-to-right method of binary exponentiation, we can repeatedly apply our trick at each stage of the partial computations.

Efficient algorithms for group exponentiation have a long history (see [Knuth] and [Gordon1998]), and optimal exponentiation routines typically use a combination of the left-to-right or right-to-left m-ary exponentiation with sliding window methods, addition-subtraction chains, signed representations, etc. Our procedure can be used on top of these methods for $m = 2$ to obtain a savings of up to 8.5% of the total cost of the exponentiation for curves over large prime fields, depending upon the window size and form which is used. This is described in detail in Section 4.

3.1. **Detailed Description of the Algorithm.** Here are the detailed formulae for our procedure when the curve has the form E_{simple} and all the points are distinct, none equal to $\mathbf{O}$. Figure 1 in Section 7 gives details for all characteristics. That figure also covers special cases, where an input or an intermediate result is the point at infinity.

Suppose $P = (x_1,\ y_1)$ and $Q = (x_2,\ y_2)$ are distinct points on E_{simple}, and $x_1 \neq x_2$. The point $P + Q$ will have coordinates $(x_3,\ y_3)$, where

$$\begin{aligned} \lambda_1 &= (y_2 - y_1)/(x_2 - x_1), \\ x_3 &= \lambda_1^2 - x_1 - x_2, \qquad \text{and} \\ y_3 &= (x_1 - x_3)\lambda_1 - y_1. \end{aligned}$$

Now suppose we want to add $(P + Q)$ to P. We must add $(x_1,\ y_1)$ to $(x_3,\ y_3)$ using the above rule. Assume $x_3 \neq x_1$. The result will have coordinates $(x_4,\ y_4)$, where

$$\begin{aligned} \lambda_2 &= (y_3 - y_1)/(x_3 - x_1), \\ x_4 &= \lambda_2^2 - x_1 - x_3, \qquad \text{and} \\ y_4 &= (x_1 - x_4)\lambda_2 - y_1. \end{aligned}$$

We can omit the y_3 computation, because it is used only in the computation of λ_2, which can be computed without knowing y_3 as follows:

$$\lambda_2 = -\lambda_1 - 2y_1/(x_3 - x_1).$$

Omitting the y_3 computation saves a field multiplication. Each λ_2 formula requires a field division, so the overall saving is this field multiplication.

This trick can also be applied to save one multiplication when computing $3P$, the triple of a point $P \neq \mathbf{O}$, where the λ_2 computation will need the slope of a line through two distinct points $2P$ and P.

This trick can be used twice to save 2 multiplications when computing $3P + Q = ((P + Q) + P) + P$. Thus $3P + Q$ can be computed using 1 multiplication, 3 squarings, and 3 divisions. Such a sequence of operations would be performed repeatedly if an exponent were written in ternary form and left-to-right exponentiation were used. Ternary representation performs worse than binary representation for large random exponents k, but the operation of triple and add might be useful in another context.

A similar trick works for elliptic curve arithmetic in characteristic 2, as is shown in the pseudocode for this routine given in Figure 1.

Table 1 summarizes the costs of some operations on E_{simple}.

TABLE 1. Costs of simple operations on E_{simple}

Doubling	$2P$	2 squarings, 1 multiplication, 1 division
Add	$P \pm Q$	1 squaring, 1 multiplication, 1 division
Double-add	$2P \pm Q$	2 squarings, 1 multiplication, 2 divisions
Tripling	$3P$	3 squarings, 1 multiplication, 2 divisions
Triple-add	$3P \pm Q$	3 squarings, 1 multiplication, 3 divisions

4. Comparison to Conventional Exponentiation

In this section we analyze the performance of our algorithm compared to conventional left-to-right exponentiation. We will refer to adding two distinct points on the curve E as elliptic curve addition, and to adding a point to itself as elliptic curve doubling. Suppose we would like to compute kP_0 given k and P_0, where the exponent k has n bits and n is at least 160.

Assume that the relative costs of field operations are 1 unit per squaring or general multiplication and α units per inversion. [BSS, p. 72] assumes that the cost of an inversion is between 3 and 10 multiplications. In some implementations the relative cost of an inversion depends on the size of the underlying field. Our own timings on a Pentium II give a ratio of 3.8 for a 160-bit prime field and 4.8 for a 256-bit prime field when not using Montgomery multiplication. Some hardware implementions for fast execution of inversion in binary fields yield inversion/multiplication ratios of 4.18 for 160-bit exponents and 6.23 for 256-bit exponents [KoçSav2002].

The straightforward left-to-right binary method of exponentiation needs about n elliptic curve doublings. If the window size is one, then for every 1-bit in the binary representation, we perform an elliptic curve doubling followed directly by an elliptic curve addition. Suppose about half of the bits in the binary representation of k are 1's. Then forming kP consists of performing $n/2$ elliptic curve doublings and $n/2$ elliptic curve additions.

In general, independent of the window size, the number of elliptic curve doublings to be performed will be about n asymptotically, whereas the number of elliptic curve additions to be performed will depend on the window

size. Define the value $0 < \varepsilon < 1$ for a given window size to be such that the number of elliptic curve additions to be performed is εn on average. For example with window size 1, ε is 1/2.

If we fix a window size and its corresponding ε, then the conventional algorithm for exponentiation needs about $2n + \varepsilon n$ field squarings, $n + \varepsilon n$ field general multiplications, and $n + \varepsilon n$ field divisions. If one inversion costs α multiplications, then the cost of a division is $(\alpha + 1)$ multiplications. So the overall cost in field multiplications is

$$(2n + \varepsilon n) + (n + \varepsilon n) + (\alpha + 1)(n + \varepsilon n) = (4 + \alpha)n + (3 + \alpha)\varepsilon n.$$

Now we analyze the percentage savings obtained by our algorithm, not including precomputation costs. The above computation includes εn sub-computations of the form $2P_1 + P_2$. Writing each as $P_1 + (P_1 + P_2)$ saves one squaring per sub-computation, reducing the overall cost to $(4 + \alpha)n + (2 + \alpha)\varepsilon n$. The technique in Section 3 saves another multiplication per sub-computation, dropping the overall cost to $(4 + \alpha)n + (1 + \alpha)\varepsilon n$. This means we get a savings of

$$2\varepsilon/((4 + \alpha) + (3 + \alpha)\varepsilon).$$

When the window size is 1 and the inversion/multiplication ratio α is assumed to be 4.18, this gives a savings of 8.5%. When α is assumed to be 6.23, we still obtain a savings of 6.7%. When the window size is 2 and $2P$ and $3P$ have been precomputed, we find that $\varepsilon = 3/8$. So when α is 4.18, we get a savings of 6.9%, and when α is 6.23, we still obtain a savings of 5.5%. Similarly if the window size is 4, and we have precomputed small multiples of P, we still achieve a savings of 3.8% to 4.8%, depending on α.

Another possibility is using addition/subtraction chains and higher-radix methods. The binary method described in [IEEE, section A.10.3] utilizes addition/subtraction chains and does about $2n/3$ doublings and $n/3$ double-adds (or double-subtracts), so $\varepsilon = 1/3$ in this case. (See [Gordon1998, section 2.3] for an explanation of how we obtain $\varepsilon = 1/3$ in this case.) With $\alpha = 4.18$, we get a 6.3% improvement.

Exponentiation algorithms that use both addition/subtraction chains and sliding window size may have lower ε, but we still obtain at least a 4.2% savings if $\varepsilon > 0.2$ and $\alpha = 4.18$.

[SaSa2001, Section 3.3] presents some possible trade-offs arising from different inversion/multiplication ratios. We discuss this further in Section 5.3.

5. Examples and Applications

5.1. **Left-to-right binary exponentiation.** Suppose we would like to compute $1133044P = (100010100100111110100)_2 P$ with left-to-right binary exponentiation. We will do this in two ways, the standard way and the way that uses our improvements. For both methods, we assume that $3P$ has been precomputed. The following table compares the number of operations needed (a = point additions, d = point doublings, div = field divisions, s =

field squarings, m = field multiplies)

	standard implementation	improvements
$1133044P = 4(283261P)$	$2d$	$2d$
$283261P = 128(2213P) - 3P$	$7d + 1a$	$6d + 2a$(save $1m$)
$2213P = 8(277P) - 3P$	$3d + 1a$	$2d + 2a$(save $1m$)
$277P = 8(35P) - 3P$	$3d + 1a$	$2d + 2a$(save $1m$)
$35P = 8(4P) + 3P$	$3d + 1a$	$2d + 2a$(save $1m$)
$4P = P + 3P$	$1a$	$1a$
Total:	$23div + 41s + 23m$	$23div + 37s + 19m$

This saves 4 squarings and 4 multiplications. Estimating the division cost at about 5 multiplications, this savings translates to about 4.47%.

5.2. **Simultaneous multiple exponentiation.** Another use of our improved elliptic curve double-add technique is multiple exponentiation, such as $k_1P_1 + k_2P_2 + k_3P_3$, where the three exponents k_1, k_2, and k_3 have approximately the same length. One algorithm creates an 8-entry table with

$$\mathbf{O}, \quad P_1, \quad P_2, \quad P_2 + P_1, \quad P_3, \quad P_3 + P_1, \quad P_3 + P_2, \quad P_3 + P_2 + P_1.$$

Subsequently it uses one elliptic curve doubling followed by the addition of a table entry, for each bit in the exponents [Möller2001]. About 7/8 of the doublings will be followed by an addition other than $\mathbf{O}$.

To form $29P_1 + 44P_2$, for example, write the exponents in binary form: $(011101)_2$ and $(101100)_2$. Scanning these left-to-right, the steps are

Bits	Table entry	Action
$0, 1$	P_2	$T := P_2$
$1, 0$	P_1	$T := 2T + P_1 = P_1 + 2P_2$
$1, 1$	$P_1 + P_2$	$T := 2T + (P_1 + P_2) = 3P_1 + 5P_2$
$1, 1$	$P_1 + P_2$	$T := 2T + (P_1 + P_2) = 7P_1 + 11P_2$
$0, 0$	$\mathbf{O}$	$T := 2T = 14P_1 + 22P_2$
$1, 0$	P_1	$T := 2T + P_1 = 29P_1 + 44P_2$

There is one elliptic curve addition $(P_1 + P_2)$ to construct the four-entry table, four doublings immediately followed by an addition, and one doubling without an addition. While doing 10 elliptic curve operations, the technique in this paper is used four times. Doing the exponents separately, say by the addition-subtraction chains

$$1, 2, 4, 8, 7, 14, 28, 29 \qquad \text{and} \qquad 1, 2, 4, 6, 12, 24, 48, 44$$

takes seven elliptic curve operations per chain, plus a final add (15 total).

5.3. **Elliptic curve method of factorization.** The Elliptic Curve Method (ECM) of factoring a composite integer N chooses an elliptic curve E with coefficients modulo N. It does some exponentiation, working in the ring $\mathbb{Z}/N\mathbb{Z}$ rather than over a field. The algorithm may encounter a zero divisor while trying to invert a nonzero element, but that is good, because it leads to a factorization of N. In this application, only the x-coordinate of the exponentiation is required.

[Mont1987, pp. 260ff] proposes a parameterization, $By^2 = x^3 + Ax^2 + x$, which uses no inversions during an exponentiation but omits the y-coordinate of the result. Its associated costs for computing the x-coordinate are

$P + Q$ from P, Q, $P - Q$	2 squarings, 4 multiplications
$2P$ from P	2 squarings, 3 multiplications

To form kP from P for a large n-bit integer k, this method uses about $4n$ squarings and $7n$ multiplications, working from the binary representation of k. Some variations [Mont2002] use fewer steps but are harder to program.

In contrast, using the technique described in this paper combined with the method described in [IEEE, section A.10.3], we do about $2n/3$ doublings and $n/3$ double-adds (or double-subtracts). Using our improved technique, by Table 1, the estimated cost of the exponentiation is $2n$ squarings, n multiplications and $4n/3$ divisions.

The technique in this paper is superior if $4n/3$ divisions cost less than $2n$ squarings and $6n$ multiplications. A division can be implemented as an inversion plus a multiplication, so the new technique is superior if an inversion is cheaper than 1.5 squarings and 3.5 multiplications.

[Mont1987] observes that one may trade two independent inversions for one inversion and three multiplications, using $x^{-1} = y(xy)^{-1}$ and $y^{-1} = (xy)^{-1}x$. When using many curves to (simultaneously) tackle the same composite integer, the asymptotic cost per inversion drops to 3 multiplications. We anticipate an improvement by using this along with our technique.

6. Application to Weil and Tate pairings

The Weil and Tate pairings are becoming important for public-key cryptography [Joux2002]. The algorithms for these pairings construct rational functions with a prescribed pattern of poles and zeroes. An appendix to [BoFr2001] describes Miller's algorithm for computing the Weil pairing on an elliptic curve in detail.

Fix an integer $m > 0$ and an m-torsion point P on an elliptic curve E. Let f_1 be any nonzero field element. For an integer $c > 1$, let f_c be a function on E with a c-fold zero at P, a simple pole at cP, a pole of order $c - 1$ at $\mathbf{O}$, and no other zeroes or poles. When $c = m$, this means that f_m has an m-fold zero at P and a pole of order m at $\mathbf{O}$. Corollary 3.5 on page 67 of [Silverman] asserts that such a function exists. This f_c is unique up to a nonzero multiplicative scalar. Although f_c depends on P, we omit the extra subscript P unless there is some ambiguity.

The Tate pairing evaluates a quotient of the form $f_m(Q_1)/f_m(Q_2)$ for two points Q_1, Q_2 on E (see, for example, [BKLS2002]). (The Weil pairing has two such computations.) Such evaluations can be done iteratively using an addition/subtraction chain for m, once we know how to construct f_{b+c} and f_{b-c} from $(f_b,\ bP)$ and $(f_c,\ cP)$. Let $g_{b,c}$ be the line passing through the points bP and cP. When $bP = cP$, this is the tangent line to E at bP. Let g_{b+c} be the vertical line through $(b+c)P$ and $-(b+c)P$. Then we have the useful formulae

$$f_{b+c} = f_b \cdot f_c \cdot \frac{g_{b,c}}{g_{b+c}} \qquad \text{and} \qquad f_{b-c} = \frac{f_b \cdot g_b}{f_c \cdot g_{-b,c}}.$$

Denote $h_b = f_b(Q_1)/f_b(Q_2)$ for each integer b. Although f_b was defined only up to a multiplicative constant, h_b is well-defined. We have

(1)
$$h_{b+c} = h_b \cdot h_c \cdot \frac{g_{b,c}(Q_1) \cdot g_{b+c}(Q_2)}{g_{b,c}(Q_2) \cdot g_{b+c}(Q_1)} \quad \text{and} \quad h_{b-c} = \frac{h_b \cdot g_b(Q_1) \cdot g_{-b,c}(Q_2)}{h_c \cdot g_b(Q_2) \cdot g_{-b,c}(Q_1)}.$$

So far in the literature, only the f_{b+c} formula appears, but the f_{b-c} formula is useful if using addition/subtraction chains. The addition/subtraction chain iteratively builds h_m along with mP.

6.1. **Using the double/add trick with parabolas.** We now describe an improved method for obtaining $(h_{2b+c},\ (2b+c)P)$ given $(h_b,\ bP)$ and $(h_c,\ cP)$. The version of Miller's algorithm described in [BKLS2002] uses left-to-right binary exponentiation with window size one. That method would first compute $(h_{2b},\ 2bP)$ and later $(h_{2b+c},\ (2b+c)P)$. We propose to compute $(h_{2b+c},\ (2b+c)P)$ directly, producing only the x-coordinate of the intermediate point $bP + cP$. To combine the two steps, we construct a parabola through the points bP, bP, cP, $-2bP - cP$.

To form f_{2b+c}, we combine forming f_{b+c} with f_{b+c+b}: the latter can be expressed as

$$f_{2b+c} = f_{b+c} \cdot \frac{f_b \cdot g_{b+c,b}}{g_{2b+c}} = \frac{f_b \cdot f_c \cdot g_{b,c}}{g_{b+c}} \cdot \frac{f_b \cdot g_{b+c,b}}{g_{2b+c}} = \frac{f_b \cdot f_c \cdot f_b}{g_{2b+c}} \cdot \frac{g_{b,c} \cdot g_{b+c,b}}{g_{b+c}}.$$

We replace $(g_{b,c} \cdot g_{b+c,b})/g_{b+c}$ by the parabola, whose formula is given below. Evaluate the formula for f_{2b+c} at Q_1 and Q_2 to get a formula for h_{2b+c}.

6.2. **Equation for parabola through points.** If R and S are points on an elliptic curve E, then there is a (possibly degenerate) parabolic equation passing through R twice (i.e., tangent at R) and also passing through S and $-2R - S$. Using the notations $R = (x_1,\ y_1)$ and $S = (x_2,\ y_2)$ with $R + S = (x_3,\ y_3)$ and $2R + S = (x_4, y_4)$, a formula for this parabola is

$$\frac{(y + y_3 - \lambda_1(x - x_3))(y - y_3 - \lambda_2(x - x_3))}{x - x_3}. \tag{2}$$

The left half of the numerator of (2) is a line passing through R, S, and $-R-S$ whose slope is λ_1. The second half of the numerator is a line passing

through $R+S$, R, and $-2R-S$, whose slope is λ_2. The denominator is a (vertical) line through $R+S$ and $-R-S$. The quotient has zeros at R, R, S, $-2R-S$ and a pole of order four at $\mathbf{O}$.

We simplify (2) by expanding it in powers of $x-x_3$. Use the equation for E to eliminate references to y^2 and y_3^2.

$$\begin{aligned} &\tfrac{y^2-y_3^2}{x-x_3} - \lambda_1(y-y_3) - \lambda_2(y+y_3) + \lambda_1\lambda_2(x-x_3) \\ &= x^2 + xx_3 + x_3^2 + a + \lambda_1\lambda_2(x-x_3) - \lambda_1(y-y_3) - \lambda_2(y+y_3) \\ &= x^2 + (x_3+\lambda_1\lambda_2)x - (\lambda_1+\lambda_2)y + \text{constant}. \end{aligned} \tag{3}$$

Knowing that (3) passes through $R=(x_1,y_1)$, one succinct formula for the parabola is

$$(x-x_1)(x+x_1+x_3+\lambda_1\lambda_2) - (\lambda_1+\lambda_2)(y-y_1). \tag{4}$$

In the previous section we can now replace $(g_{b,c}\cdot g_{b+c,b})/g_{b+c}$ by the parabola (4) with $R=bP$ and $S=cP$.

Formula (4) for the parabola does not reference y_3 and is never identically zero since its x^2 coefficient is 1. Figure 1 gives a formula for this parabola in degenerate cases, as well as for the more general curve (6).

6.3. **Savings.** We claim the pairing algorithm needs less effort to evaluate a parabola at a point than to evaluate lines and take their product at that point. The parabola does not reference y_3, so we won't need to compute the y-coordinate of $bP+cP$ and can use the double-add trick.

Here is a precise analysis of the savings we obtain by using the parabola when computing the Tate pairing. Again assume that we use the binary method described in [IEEE, section A.10.3] to form mP, where m has n bits. (It does $2n/3$ doublings and $n/3$ double-adds or double-subtracts.) We manipulate the numerator and denominator of h_j separately, doing one inversion $h_j = h_{\text{num},j}/h_{\text{denom},j}$ at the very end.

Analysis of doubling step: The analysis of the doubling step is the same in the standard and in the new algorithms. Suppose we want to compute $(h_{2b},\ 2bP)$ from $(h_b,\ bP)$. We need an elliptic curve doubling to compute $2(bP)$, after which we apply (1). If $bP=(x_1,\ y_1)$ and $2bP=(x_4,\ y_4)$ then

$$\frac{g_{b,b}}{g_{2b}} = \frac{y-y_1-\lambda_1(x-x_1)}{x-x_4}. \tag{5}$$

The computation of the coefficients in (5) is free since λ_1 is known. Evaluating (5) at Q_1 and Q_2 (keeping numerators and denominators separate) costs two multiplications. Multiplying four fractions in (1) costs 6 more multiplications (or squarings). The total cost is $3+2+6=11$ field multiplications and one field division.

Analysis of double-add step: The standard algorithm performs one doubling followed by an addition to compute $(h_{2b+c},\ (2b+c)P)$ from $(h_b,\ bP)$ and $(h_c,\ cP)$. Similar to the above analysis we can compute the cost as 21

field multiplications and 2 divisions. [The cost would be one multiplication less if one does two elliptic curve additions: $(2b+c)P = (bP + cP) + bP$.]

The new algorithm does one elliptic curve double-add operation. It costs only one multiplication to construct the coefficients of the parabola (4), because we computed λ_1 and λ_2 while forming $(2b+c)P$. Evaluating the parabola (and the vertical line g_{2b+c}) twice costs four multiplications. Multiplying five fractions costs another 8 multiplications. The total cost is $3 + 1 + 4 + 8 = 16$ field multiplications and 2 field divisions.

Total savings: Estimating a division as 5.18 multiplications, the standard algorithm for $(h_m,\ mP)$ takes $(16.18 \cdot 2n/3) + (31.36 \cdot n/3) = (21.24)n$ steps, compared to $(16.18 \cdot 2n/3) + (26.36 \cdot n/3) = 19.57n$ steps for the new method, a 7.8% improvement. A Weil pairing algorithm using the parabola will also save 7.8% over Miller's algorithm, because we can view the Weil pairing as "two applications of the Tate pairing", each saving 7.8%.

Sometimes (e.g., [BLS2001]) one does multiple Tate pairings with P fixed but varying Q_1 and Q_2. If one has precomputed all coefficients of the lines and parabolas, then the costs of evaluation are 8 multiplications per doubling step or addition step, and 12 multiplications per combined double-add step. The overall costs are $32n/3$ multiplications per evaluation with the traditional method and $28n/3$ multiplications with the parabolas, a 12.5% improvement.

7. Pseudocode

The general Weierstrass form for the equation of an elliptic curve is:

$$E : y^2 + a_1xy + a_3y = x^3 + a_2x^2 + a_4x + a_6, \tag{6}$$

subject to the condition that the coefficients a_1, a_2, a_3, a_4, a_6 satisfy a certain inequality to prevent singularity [Silverman, p. 46]. The negative of a point $P = (x_1,\ y_1)$ on (6) is $-P = (x_1,\ -a_1x_3 - a_3 - y_1)$. [This seems to require a multiplication a_1x_3, but in practice a_1 is 0 or 1.] If $P = (x_1,\ y_1)$ is a finite point on (6), then the tangent line at P has slope

$$\lambda_1 = \frac{3x_1^2 + 2a_2x_1 + a_4 - a_1y_1}{2y_1 + a_1x_1 + a_3}. \tag{7}$$

Figure 1 gives the pseudocode for implementing the savings for an elliptic curve of this general form.

Figure 1.
Algorithm for computing $2P + Q$ and the equation for a parabola through P, P, Q, and $-(2P+Q)$, where $P = (x_1, y_1)$ and $Q = (x_2, y_2)$.

```
if (P = O) then
    if (Q = O) then
        parabola = 1;
    else
        parabola = x − x_2;
    end if
    return Q;
else if (Q = O) then
    if (denominator of (7) is zero) then
        parabola = x − x_1;
        return O;
    end if
    Get tangent slope λ_1 from (7);
    parabola = y − y_1 − λ_1(x − x_1);
    x_3 = λ_1(λ_1 + a_1) − a_2 − 2x_1;
    y_3 = λ_1(x_1 − x_3) − a_1 x_3 − a_3 − y_1;
    return (x_3, y_3);
else
    if (x_1 ≠ x_2) then
        λ_1 = (y_1 − y_2)/(x_1 − x_2);   /* slope of line through P, Q.  */
    else if (y_1 ≠ y_2 OR denominator of (7) is zero) then
        parabola = (x − x_1)^2;
        return P;   /* P and Q must be negatives, so 2P + Q = P.*/
    else
        Get tangent slope λ_1 from (7);
    end if
    x_3 = λ_1(λ_1 + a_1) − a_2 − x_1 − x_2;
        /* Think y_3 = λ_1(x_1 − x_3) − a_1 x_3 − a_3 − y_1.   */
    if (x_3 = x_1) then
        parabola = y − y_1 − λ_1(x − x_1);
        return O;   /* P + Q and P are negatives.  */
    end if   /* Think λ_2 = (y_1 − y_3)/(x_1 − x_3) */
    λ_2 = (a_1 x_3 + a_3 + 2y_1)/(x_1 − x_3) − λ_1;
    x_4 = λ_2(λ_2 + a_1) − a_2 − x_1 − x_3;
    y_4 = λ_2(x_1 − x_4) − a_1 x_4 − a_3 − y_1;
    parabola = (x − x_1)(x − x_4 + (λ_1 + λ_2 + a_1)λ_2) − (λ_1 + λ_2 + a_1)(y − y_1);
    return (x_4, y_4);
end if
```
