## Abstract

In this paper we propose a very efficient (string)  $OT_n^1$  scheme for any  $n \geq 2$ . We build our  $OT_n^1$  scheme from fundamental cryptographic techniques directly. It achieves optimal efficiency in the number of rounds and the total number of exchanged messages for the case that the receiver's choice is unconditionally secure. The computation time of our  $OT_n^1$  scheme is very efficient, too. The receiver need compute 2 modular exponentiations only no matter how large  $n$  is, and the sender need compute  $2n$  modular exponentiations. Furthermore, the system-wide parameters need not change during the lifetime of the system and are *universally usable*. That is, all possible receivers and senders use the same parameters and need no trapdoors specific to each of them. For our  $OT_n^1$  scheme, the privacy of the receiver's choice is unconditionally secure and the privacy of the un-chosen secrets is at least as strong as the hardness of the decisional Diffie-Hellman problem.

We extend our  $OT_n^1$  scheme to distributed oblivious transfer schemes. Our distributed  $OT_n^1$  scheme takes full advantage of the research results of secret sharing and is conceptually simple. It achieves better security than Noar and Pinkas's scheme does in many aspects. For example, our scheme is secure against collusion of  $R$  and  $t-1$  servers and it need not restrict  $R$  to contact at most  $t$  servers, which is difficult to enforce.

For applications, we present a method of transforming any single-database PIR protocol into a symmetric PIR protocol with only one extra unit of communication cost.

Keywords: oblivious transfer, distributed oblivious transfer, private information retrieval.

## 1 Introduction

Consider two parties of the sender  $S$  and the receiver  $R$ .  $S$  has  $n$  secrets  $m_1, m_2, \dots, m_n$  and is willing to disclose one of them ( $m_\alpha$ ) to  $R$  at  $R$ 's choice  $\alpha$ . However,  $R$  does not want to reveal to  $S$  its choice  $\alpha$  and  $S$  does not want  $R$  to gain any information about other secrets  $m_i$ ,  $i \neq \alpha$ . An oblivious transfer scheme is a cryptographic two-party protocol that provides a solution for the

goal. Oblivious transfer has many flavors, such as, original oblivious transfer ( $OT$ ), 1-out-2 oblivious transfer ( $OT_2^1$ ) and 1-out- $n$  oblivious transfer ( $OT_n^1$ ).

Rabin [31] proposes the concept of oblivious transfer ( $OT$ ) in the cryptographic scenario. In this case,  $S$  has only one secret (bit)  $m$  and would like to have  $R$  to get it with probability 0.5. On the other hand,  $R$  does not want  $S$  to know whether it gets  $m$  or not. For  $OT_2^1$ ,  $S$  has two secrets  $m_1$  and  $m_2$  and would like to have  $R$  to get one of them at  $R$ 's choice. Again,  $R$  does not want  $S$  to know which secret it chooses.  $OT_n^1$  is a natural extension of  $OT_2^1$  to the case of  $n$  secrets. Nevertheless, to construct  $OT_n^1$  from  $OT_2^1$  is not trivial.  $OT_n^1$  is also known as "all-or-nothing disclosure of secrets (ANDOS)" in which  $R$  is not allowed to gain combined information of the secrets, such as, their exclusive-or. Essentially, all these flavors are equivalent in the information theoretic sense [9, 12, 15]. Oblivious transfer is a fundamental primitive for cryptography and secure distributed computation [23, 24] and has many applications, such as, private information retrieval (PIR), fair electronic contract signing, oblivious secure computation, etc [5, 14, 21].

A general approach for constructing  $OT_n^1$  schemes is first to construct a basis  $OT_2^1$  scheme (where  $m_1$  and  $m_2$  are bits) and then to construct the  $OT_n^1$  scheme by (explicitly or implicitly) invoking the basis  $OT_2^1$  scheme for many runs, typically,  $n$  or  $\log_2 n$  runs [9, 11, 26]. Another approach is to build  $OT_n^1$  schemes from basic techniques directly [29, 30, 33, 35].

In this paper we propose a very efficient  $OT_n^1$  scheme for any  $n \geq 2$  even when the secrets  $m_i$ 's are strings. We build our  $OT_n^1$  scheme from fundamental cryptographic techniques directly. It achieves optimal efficiency in the number of rounds and the total number of exchanged messages for the case that  $R$ 's choice is unconditionally secure. The computation time of our  $OT_n^1$  scheme is very efficient, too.  $R$  need compute 2 modular exponentiations only no matter how large  $n$  is, and  $S$  need compute  $2n$  modular exponentiations. Furthermore, the system-wide parameters need not change during the lifetime of the system and are *universally usable*. That is, all possible  $R$ 's and  $S$ 's use the same parameters and need no trapdoors (eg. factoring of  $N = pq$ ) specific to each of them. For our  $OT_n^1$  scheme, the privacy of  $R$ 's choice  $\alpha$  is unconditionally secure and the privacy of the un-chosen secrets  $m_i$ ,  $i \neq \alpha$ , is at least as strong as the hardness of the decisional Diffie-Hellman problem.

Our  $OT_n^1$  scheme can be parallelized to construct an  $OT_n^k$  scheme, in which  $R$  can get  $k$  secrets among  $n$  secrets at its choice. Our  $OT_n^k$  schemes are very efficient, too.

Furthermore, we can combine our  $OT_n^1$  scheme with any secret sharing scheme to form an efficient threshold (distributed) oblivious transfer scheme. The concept of threshold (distributed) oblivious transfer is formally proposed by Noar and Pinkas [28], though it was used in some other contents [32]. For distributed oblivious transfer, there are  $p$  servers additionally. Each server holds partial information about the secrets  $m_i$ 's. If  $R$  contacts  $t$  (the threshold) or more servers, it can compute  $m_\alpha$  of its choice; otherwise, it cannot get any information about the secrets.  $R$ 's choice should not be revealed by a coalition of  $t'$  servers for some threshold  $t' \leq p$ . Our threshold  $OT_n^1$  scheme takes full advantage of the research results of secret sharing and is conceptually simple. It achieves better security than Noar and Pinkas's scheme does in many aspects. For example, our scheme is secure against collusion of  $R$  and  $t-1$  servers and it need not restrict  $R$  to contact at most  $t$  servers, which is difficult to enforce.

In the end we further extend threshold oblivious transfer to access-structure oblivious transfer ( $\Gamma\text{-}OT_n^k$ ). Our  $\Gamma\text{-}OT_n^1$  scheme is very efficient, too.

For applications, we present a method of transforming any single-database PIR protocol into a symmetric PIR (SPIR) protocol with only one extra unit of communication cost. As SPIR is equivalent to  $OT_n^1$ , this transformation provides a reduction from PIR to  $OT_n^1$  with almost no extra communication cost. In particular, any computational PIR [25], in which the receiver's choice is computationally private, with efficient communication complexity can be transformed to an  $OT_n^1$  scheme (with  $R$ 's choice is computationally secure) with almost the same efficiency for communication complexity. Some communication-efficient single-database PIR schemes have been proposed [13, 25].

## 1.1 Previous work and comparison

Oblivious transfer has been studied in various flavors and security models extensively (cf. [1, 4, 7, 9, 11, 17, 21, 26, 30, 33, 35]). In particular, bit  $OT_2^1$  (where  $m_1$  and  $m_2$  are bits) attracts much attention from researchers since it is the basis oblivious transfer scheme to which string  $OT_2^1$  and  $OT_n^1$  schemes are reduced. Most previous oblivious transfer schemes are based on hardness of factoring or quadratic residuosity problems except the one in [4], which is based on hardness of computing discrete logarithm.

The reduction approach is studied in [8, 9, 11, 15, 26]. For example, a  $k$ -bit string  $OT_2^1$  scheme can be achieved by invoking  $\beta k$  runs of a bit  $OT_2^1$  scheme for some  $\beta$ ,  $2 \leq \beta \leq 18$ , [8, 9, 11]. In [26], a string  $OT_n^1$  scheme is constructed by invoking  $\log_2 n$  runs of a string  $OT_2^1$  scheme.

The generic construction is studied in [21, 30, 33, 35, 29]. In particular, Stern [35] proposes a general construction for  $OT_n^1$  based on any public-key encryption scheme that has some specific properties, such as, the property of "additive" homomorphism. The privacy of the receiver's choice of the scheme is computationally secure. Stern focuses on providing a zero-knowledge proof for verifying that  $n$  committed bits consist of exact one 1 and  $n - 1$  0's. The numbers of rounds and exchanged messages are less efficient than ours with the same measuring parameters. For example, the scheme takes  $O(\sqrt{\log_2 n})$  rounds if better efficiency for exchanged messages is desired.

Naor and Pinkas [29] proposes the first two-round oblivious transfer protocol, which achieves unconditional security for the sender's choice also. In comparison, the system parameter of our protocol is a constant, while theirs is  $O(n)$ . Furthermore, our protocol can be extended to threshold oblivious transfer easily and transfer any PIR protocol into a SPIR protocol without increasing communication complexity.

Distributed oblivious transfer has been studied in various contents under variant models, such as function evaluation [3] and private information retrieval [22]. Naor and Pinkas [28] identify the important attributes of distributed oblivious transfer. They propose a threshold (string)  $OT_2^1$  scheme such that  $R$  and the involved servers need do polynomial evaluation only. Nevertheless, it comes with cost of privacy and simplicity. For example, a coalition of less than  $t$  servers can compute  $R$ 's choice. One scheme (based on sparse polynomials) is not secure against collusion of  $R$  and a single server. Some schemes cannot prevent  $R$  from learning linear combination of secrets. Furthermore  $R$  cannot contact more than  $t$  servers; otherwise, the scheme is not secure.

In some sense, our schemes fall in the category of non-interactive oblivious transfer [4, 34], in which  $R$  selects a public key and  $S$  performs non-interactive oblivious transfer using  $R$ 's public key. The schemes in [34] are based on the quadratic residuosity assumption. Each  $R$  uses a specific Blum integer  $N$  that is re-usable by the  $R$ . The privacy of  $R$ 's choice is computationally secure and the privacy of the un-chosen secret is unconditionally secure. The bit  $OT_2^1$  scheme is extended to the bit  $OT_n^1$  scheme. The  $k$ -bit string  $OT_2^1$  scheme invokes  $k$  runs of the bit  $OT_2^1$  scheme. The number (size) of exchanged messages is not as efficient as ours. For example, if  $k$  is close to the security parameter, our  $k$ -bit string  $OT_2^1$  scheme exchanges  $O(k)$  bits and that of [34] exchanges  $O(k^2)$  bits.

Transforming any PIR scheme to a symmetric PIR scheme has been studied in [19, 26]. Naor and Pinkas [26] show such a reduction using one call to the base PIR scheme and a logarithmic number of calls to a string  $OT_2^1$  scheme. Crescenzo, etc [19], show a reduction using communication  $poly(k)$  times of that of the base PIR scheme, where  $k$  is the security parameter. In comparison, our reduction uses only one extra communication cost.

## 2 1-out-n Oblivious Transfer

An  $OT_n^1$  scheme is a two-party protocol in which the sender  $S$  possesses  $n$  (string) secrets  $m_1, m_2, \dots, m_n$  and would like to reveal one of them to the receiver  $R$  at  $R$ 's choice. We assume that  $S$  is honest, that is, it won't send secrets that are not the same as claimed ones, either in content or in order. An  $OT_n^1$  scheme should meet the following requirements:

1. Correctness: if both  $R$  and  $S$  follow the protocol,  $R$  gets  $m_\alpha$  after executing the protocol with  $S$ , where  $\alpha$  is its choice.
2. Receiver's privacy: after executing the protocol with  $R$ ,  $S$  shall not get information about  $R$ 's choice  $\alpha$ .
3. Sender's privacy: after executing the protocol with  $S$ ,  $R$  gets no information about other  $m_i$ 's or their combinations,  $i \neq \alpha$ ,

Let  $g$  and  $h$  be two generators in  $G_q$ , which is an order- $q$  group, where  $q$  is prime. Let  $x \in_R X$  denote that  $x$  is chosen uniformly and independently from the set  $X$ . We assume that the decisional Diffie-Hellman (DDH) problem over  $G_q$  is hard. That is, it is not possible to distinguish the following two distribution ensembles with a non-negligible advantage in polynomial time:

- $D = \{D_{G_q}\} = \{(g, g^a, g^b, g^{ab})\}_{G_q}$ , where  $g \in_R G_q \setminus \{1\}$  and  $a, b \in_R \mathbb{Z}_q$ ;
- $R = \{R_{G_q}\} = \{(g, g^a, g^b, g^c)\}_{G_q}$ , where  $g \in_R G_q \setminus \{1\}$  and  $a, b, c \in_R \mathbb{Z}_q$ .

For simplicity, we omit the security parameter  $\text{size}(q)$  in the later arguments. Note that the DDH assumption is stronger than the discrete logarithm assumption. Typically,  $G_q$  is the set of quadratic residues of  $\mathbb{Z}_p^*$ , where  $p = 2q + 1$  is also prime. Any element in  $G_q \setminus \{1\}$  is a generator of  $G_q$ .

The system-wide parameters are  $(g, h, G_q)$ , which can be used by all possible senders and receivers. Assume that the discrete logarithm  $\log_g h$  is unknown to all. As long as  $\log_g h$  is not revealed,  $g$  and  $h$  can be used repeatedly. Our  $OT_n^1$  scheme is as follows. Wlog, we assume that the secrets  $m_i$ 's are all in  $G_q$ .

**OT<sub>n</sub><sup>1</sup> scheme:**

- $S$ 's input:  $m_1, m_2, \dots, m_n \in G_q$ ;  $R$ 's choice:  $\alpha$ ,  $1 \leq \alpha \leq n$ ;
- 1.  $R$  sends  $y = g^r h^\alpha$ ,  $r \in_R Z_q$ .
- 2.  $S$  sends  $c_i = (g^{k_i}, m_i(y/h^i)^{k_i})$ ,  $k_i \in_R Z_q$ ,  $1 \leq i \leq n$ ;
- 3. By  $c_\alpha = (a, b)$ ,  $R$  computes  $m_\alpha = b/a^r$ .

*Correctness.* Since  $c_\alpha = (a, b) = (g^{k_\alpha}, m_\alpha(y/h^\alpha)^{k_\alpha})$ , we have

$$b/a^r = m_\alpha(y/h^\alpha)^{k_\alpha} / (g^{k_\alpha})^r = m_\alpha(g^r h^\alpha / h^\alpha)^{k_\alpha} / (g^{k_\alpha})^r = m_\alpha.$$

*Efficiency.* The scheme takes only two rounds. This is optimal since at least  $R$  has to choose  $\alpha$  and let  $S$  know, and  $S$  has to respond to  $R$ 's request.  $R$  sends one message  $y$  to  $S$  and  $S$  sends  $n$  messages  $c_i$ ,  $1 \leq i \leq n$ , to  $R$ . This is also optimal (within a constant factor of 2) by the argument for the lower bound  $\Omega(n)$  of communication cost of the single-database PIR when  $R$ 's choice is unconditionally secure [14].

For computation,  $R$  need do 2 modular exponentiations for  $y$  and  $m_\alpha$ .  $S$  need do  $2n$  modular exponentiations for  $c_i$ , in which  $g^{k_i}$  can be pre-computed,  $1 \leq i \leq n$ . This is very efficient, too.

*Security.* The above  $OT_n^1$  scheme has the properties that the choice  $\alpha$  of  $R$  is unconditionally secure and  $R$  gets no information about any other  $m_i$ ,  $i \neq \alpha$ , if the DDH problem is hard.

**Theorem 2.1** *For the  $OT_n^1$  scheme, the choice  $\alpha$  of  $R$  is unconditionally secure.*

**Proof.** For any  $\alpha'$ , there is  $r'$  that satisfies  $y = g^{r'} h^{\alpha'}$ . Therefore,  $S$  cannot get any information about  $R$ 's  $\alpha$  even if it has unlimited computing power.  $\square$

**Theorem 2.2** *For the  $OT_n^1$  scheme, if  $R$  follows the protocol, it gets no information about  $m_i$ ,  $1 \leq i \neq \alpha \leq n$ , assuming that the DDH problem is hard. That is, all  $c_i$ 's,  $1 \leq i \neq \alpha \leq n$ , are computationally indistinguishable from a random  $z = (g, h, a, b)$ ,  $g, h \in_R G_q \setminus \{1\}$ ,  $a, b \in_R G_q$ , even if  $R$  knows the  $r$  and  $\alpha$  in  $y = g^r h^\alpha$ .*

**Proof.** Since the DDH assumption is stronger than the DL assumption,  $R$  cannot compute two different pairs of  $(r, \alpha)$  and  $(r', \alpha')$  that both satisfy  $y = g^r h^\alpha = g^{r'} h^{\alpha'}$ . Otherwise,  $R$  computes  $\log_g h = (r' - r)/(\alpha - \alpha')$ . Therefore,  $R$  cannot get two secrets.

We show that  $c_i$ ,  $i \neq \alpha$ , looks random assuming that the DDH problem is hard. Formally, we define the random variable of  $c_i$  as

$$C_i = (g, h, g^{k_i}, m_i(g^r h^{\alpha-i})^{k_i})$$

where  $k_i \in_R Z_q$ ,  $g, h \in_R G_q \setminus \{1\}$ . Note that we treat  $g$  and  $h$  as random variables in  $C_i$ . Let  $Z = (r_1, r_2, r_3, r_4)$ , where  $r_1, r_2 \in_R G_q \setminus \{1\}$  and  $r_3, r_4 \in_R G_q$ . We show that if  $C_i$  and  $Z$  are computationally distinguishable by distinguisher  $\mathcal{A}$ ,  $D$  and  $R$  of the DDH problem are computationally distinguishable by the following  $\mathcal{A}'$ , which uses  $\mathcal{A}$  as a procedure:

- Input:  $(g, u, v, w)$ ; (which is either from  $R$  or  $D$ )

1. If  $u \neq 1$ , let  $h = u$ ; otherwise, output 1 if and only if  $u = 1$ ;
2. Feed  $(g, u, v, m_i v^r w^{\alpha-i})$  to  $A$ .
3.  $A(g, u, v, m_i v^r w^{\alpha-i}) = 1$  if and only if output 1.

We can see that if  $(g, u, v, w) = (g, g^a, g^b, g^{ab})$  is from  $D$  and  $a \neq 0$ ,

$$(g, u, v, m_i v^r w^{\alpha-i}) = (g, h, g^b, m_i (g^r h^{\alpha-i})^b)$$

has the right form for  $C_i$ . If  $(g, u, v, w) = (g, g^a, g^b, g^c)$  is from  $R$  and  $a \neq 0$ ,

$$(g, h, v, m_i v^r w^{\alpha-i}) = (g, h, g^b, m_i g^{br+c(\alpha-i)})$$

is uniformly distributed over  $G_q \setminus \{1\} \times G_q \setminus \{1\} \times G_q \times G_q$ , which is  $Z$ . Therefore, if  $\mathcal{A}$  distinguishes  $C_i$  and  $Z$  with a non-negligible advantage  $\epsilon$ ,  $\mathcal{A}'$  distinguishes  $R$  and  $D$  with an advantage  $\epsilon \cdot (1 - 1/q) + 1/q$ , where  $1/q$  is the offset probability in Step 1.  $\square$

## 2.1 Without System-Wide Parameters

We can remove the requirement of using system-wide parameters  $(g, h, G_q)$ . Now,  $S$  first chooses  $g, h$  and  $G_q$ , and sends them to  $R$ , that is, the following step is added to the scheme.

0.  $S$  chooses  $(g, h, G_q)$  and sends them to  $R$ , where  $g, h \in_R G_q \setminus \{1\}$ .

Even if  $S$  knows  $\log_g h$ ,  $R$ 's choice  $\alpha$  is still unconditionally secure.

## 2.2 Forcing $R$ to obtain $m_\alpha$

$R$  may compute  $y$  of some special form such that it can compute combined information of the secrets. We don't know whether such  $y$  exists. To prevent this attack, we can require  $R$  to send a non-interactive zero-knowledge proof of knowledge of his knowing  $r$  and  $\alpha$  that satisfy  $y = g^r h^\alpha$ , denoted by NI-ZKIP( $g, h, y$ ). The new step 1 of the  $OT_n^1$  scheme becomes:

1'.  $R$  sends  $y = g^r h^\alpha$  and  $\beta = \text{NI-ZKIP}(g, h, y)$ , where  $r \in_R Z_q$ .

In this case,  $S$  should check validity of NI-ZKIP( $g, h, y$ ) in Step 2. If the check fails,  $S$  aborts the protocol. In fact, this modification results in a very secure  $OT_n^1$  scheme. We shall discuss in Section 7.

The property of forcing  $R$  to get some  $m_\alpha$  may be useful in some applications. For example, the sender can be assured that  $R$  cannot later deny that he has gotten some  $m_\alpha$ .

## 3 k-out-n Oblivious Transfer

We can have  $k$  parallel runs of the  $OT_n^1$  scheme to obtain an efficient  $OT_n^k$  scheme, which takes only two rounds.

**OT<sub>n</sub><sup>k</sup> scheme:**

- $S$ 's input:  $m_1, m_2, \dots, m_n$ ;  $R$ 's choice:  $\alpha_1, \alpha_2, \dots, \alpha_k$ , where  $1 \leq \alpha_i \leq n$ ,  $1 \leq i \leq k$ ;
- 1.  $R$  sends  $y_l = g^{r_l} h^{\alpha_l}$ ,  $r_l \in_R Z_q$ ,  $1 \leq l \leq k$ .
- 2.  $S$  sends  $c_{i,l} = (g^{k_{i,l}}, m_i (y_l / h^i)^{k_{i,l}})$ ,  $k_{i,l} \in_R Z_q$ ,  $1 \leq l \leq k$ ,  $1 \leq i \leq n$ ;
- 3. By  $c_{\alpha_l, l} = (a, b)$ ,  $R$  computes  $m_{\alpha_l} = b / a^{r_l}$ .  $1 \leq l \leq k$ .

We can show that the  $OT_n^k$  scheme has the same correctness and security properties as those of the  $OT_n^1$  scheme.

## 4 Threshold Oblivious Transfer

For a threshold  $t$ -out-of- $p$   $OT_n^1$  (or  $(t, p)$ - $OT_n^1$ ) scheme, there are three types of parties: one sender  $S$ ,  $p$  servers  $S_1, S_2, \dots, S_p$ , and one receiver  $R$ .  $S$  has  $n$  secrets  $m_1, m_2, \dots, m_n$ . It computes shares  $m_{i,j}$ ,  $1 \leq j \leq p$ , of  $m_i$ ,  $1 \leq i \leq n$ , and distributed shares  $m_{i,j}$ ,  $1 \leq i \leq n$ , to server  $S_j$ ,  $1 \leq j \leq p$ . Then,  $R$  chooses  $\alpha$ ,  $1 \leq \alpha \leq n$ , and contacts with any  $t$  or more servers to get information about the shares. By the received information,  $R$  should be able to compute  $m_\alpha$  and no others.

By [28], a  $(t, p)$ - $OT_n^1$  scheme should meet the following requirements:

1. Correctness: if  $R$  and servers follow the protocol and  $R$  receives information from  $t$  or more servers,  $R$  can compute one  $m_\alpha$ , where  $\alpha$  is its choice.
2. Sender's privacy: even if  $R$  receives information from  $t$  or more servers, it gains no information about any other  $m_i$ ,  $1 \leq i \neq \alpha \leq n$ . Furthermore, if  $R$  receives information from less than  $t$  servers, it gains no information about any  $m_i$ ,  $1 \leq i \leq n$ .
3. Receiver's privacy: there is a threshold  $t'$ ,  $t' \geq 1$ , such that no coalition of less than  $t'$  servers can gain any information about the choice  $\alpha$  of  $R$ . The threshold  $t'$  should be as large as possible.
4. Security against receiver-server collusion: after  $R$  gets  $m_\alpha$ , there is a threshold  $t''$ ,  $1 \leq t'' \leq t$ , such that no coalition of less than  $t''$  servers and  $R$  can gain any information about any other  $m_i$ ,  $1 \leq i \neq \alpha \leq n$ . The threshold  $t''$  should be as close to  $t$  as possible.

By the  $OT_n^1$  scheme in Section 2, we can easily construct a threshold  $(t, p)$ - $OT_n^1$  scheme. Our scheme can make use of any threshold secret sharing scheme. Our  $(t, p)$ - $OT_n^1$  scheme achieves  $t' = \infty$  and  $t'' = t$ . Both are optimal.

We construct our  $(t, p)$ - $OT_n^1$  scheme using the standard  $(t, p)$ -secret-sharing scheme. Let  $m_i$  be shared by the servers via polynomial  $f_i(x)$  of degree  $t-1$  such that  $f_i(0) = m_i$ ,  $1 \leq i \leq n$ . Each server  $S_j$ ,  $1 \leq j \leq p$ , holds the shares  $m_{i,j} = f_i(j)$ ,  $1 \leq i \leq n$ . By contacting  $t$  servers,  $R$  can compute  $t$  shares of  $m_{\alpha,j}$ 's and construct  $m_\alpha$ , where  $\alpha$  is  $R$ 's choice. Our  $(t, p)$ - $OT_n^1$  scheme is as follows.

**$(t, p) - OT_n^1$  scheme:**

- $S_j$ 's input:  $m_{1,j}, m_{2,j}, \dots, m_{n,j}$ ;  $R$ 's choice:  $\alpha, 1 \leq \alpha \leq n$ ;
- 1.  $R$  sends  $y = g^r h^\alpha$  to  $t$  different servers  $S_{j_1}, S_{j_2}, \dots, S_{j_t}, r \in Z_q$ ;
- 2. Each  $S_{j_l}, 1 \leq l \leq t$ , sends  $c_{i,j_l} = (g^{k_{i,j_l}}, m_{i,j_l} (y/h^i)^{k_{i,j_l}}), 1 \leq i \leq n$ , to  $R$ ;
- 3. By  $c_{\alpha,j_l} = (a_{j_l}, b_{j_l})$ ,  $R$  computes shares  $m_{\alpha,j_l} = b_{j_l}/a_{j_l}^r, 1 \leq l \leq t$ . Then,  $R$  interpolates these  $t$  shares to get

$$m_\alpha = \sum_{l=1}^t m_{\alpha,j_l} \left( \prod_{1 \leq d \neq l \leq t} \frac{j_d}{j_d - j_l} \right)$$

by Lagrange's interpolation method.

*Correctness.* If  $R$  contacts with  $t$  or more servers, it can compute  $t$  shares  $m_{\alpha,j_l}$  of  $m_\alpha, 1 \leq l \leq t$ . Therefore, it can compute  $m_\alpha$  as shown in the scheme.

*Efficiency.* The scheme takes only two rounds. This is optimal, again.  $R$  sends one message  $y$  to  $t$  servers and each contacted server  $S_j$  responds with  $n$  messages  $c_{i,j}, 1 \leq i \leq n$ . This is very efficient. For computation,  $R$  need do  $t + 1$  modular exponentiations for  $y$  and  $t$  shares  $m_{\alpha,j_l}, 1 \leq l \leq t$ , and one Lagrange interpolation for  $m_\alpha$ . Each contacted server  $S_j$  need do  $2n$  modular exponentiations for  $c_{i,j}, 1 \leq i \leq n$ .

*Security.* Our  $(t, p) - OT_n^1$  scheme has the following security properties:

1. Sender's privacy: if  $R$  contacts with  $t$  or more servers, the privacy of  $m_i, 1 \leq i \neq \alpha \leq n$ , is at least as strong as the hardness of the DDH problem. (The proof is similar to that of Theorem 2.2.) Furthermore, if  $R$  gets information from less than  $t$  servers,  $R$  cannot compute information about any  $m_i, 1 \leq i \leq n$ . This is guaranteed by the polynomial secret sharing scheme we use.
2. Receiver's privacy is unconditionally secure. Since for any  $\alpha'$ , there is  $r'$  that satisfies  $y = g^{r'} h^{\alpha'}$ . Even if the servers have unlimited computing power, they cannot compute  $R$ 's choice  $\alpha$ .
3. It is secure against collusion of  $R$  and  $t-1$  servers  $S_{r_1}, S_{r_2}, \dots, S_{r_{t-1}}$ , assuming the hardness of the DDH problem. Since for  $R$  and  $S_{r_l}, 1 \leq l \leq t-1$ , the privacy of shares  $m_{i,j}, i \neq \alpha, j \neq r_1, r_2, \dots, r_{t-1}$ , is at least as strong as the hardness of the DDH problem,  $R$  and these  $t-1$  servers cannot compute any information about other secrets  $m_i, 1 \leq i \neq \alpha \leq n$ .

#### 4.1 $(t, p) - OT_n^k$ Scheme

We can extend the  $(t, p) - OT_n^1$  scheme to a  $(t, p) - OT_n^k$  scheme easily. This is done by executing  $k$  parallel runs of the  $(t, p) - OT_n^1$  scheme, similar to the  $OT_n^k$  scheme in Section 4.

## 4.2 (p, p)-OT<sub>n</sub><sup>1</sup> Scheme

For  $(p, p)$ -OT<sub>n</sub><sup>1</sup>, we can use  $m_i = m_{i,1}m_{i,2} \cdots m_{i,p}$  to share  $m_i$ . Then,  $R$  can compute  $m_\alpha = (b_1b_2 \cdots b_p)/(a_1a_2 \cdots a_p)^r$ . It need do  $2p - 1$  modular multiplications and one modular exponentiations, which is very efficient.

## 4.3 Verifiable (t, p)-OT<sub>n</sub><sup>k</sup> Scheme

We can combine Feldman's or Peterson's verifiable secret sharing scheme and our OT<sub>n</sub><sup>k</sup> scheme to form a verifiable  $(t, p)$ -OT<sub>n</sub><sup>k</sup> scheme. In this case, the sender  $S$ , who has all  $m_i$ 's, publishes the verification values for  $m_i$ 's. Typically, the verification values for the shares of  $m_i$  are  $g^{a_0}, g^{a_1}, \dots, g^{a_{t-1}}$ , where  $m_i$  is shared via a degree- $(t-1)$  polynomial  $f_i(x) = m_i + a_1x + a_2x^2 + \cdots + a_{t-1}x^{t-1}$ . After computing  $m_{\alpha,ji}$ ,  $1 \leq l \leq t$ ,  $R$  can verify these shares using the verification values published by  $S$ .

# 5 Access-Structure Oblivious Transfer

Let  $\Gamma = \{\gamma_1, \gamma_2, \dots, \gamma_z\}$  be a monotonic access structure over  $p$  servers  $S_1, S_2, \dots, S_p$ . Each  $\gamma_i = \{S_{i_1}, S_{i_2}, \dots, S_{i_l}\}$  is an authorized set of servers such that all servers in  $\gamma_i$  together can construct the shared secret. Assume that  $n$  messages  $m_1, m_2, \dots, m_n$  are shared according to  $\Gamma$  by some secret sharing scheme  $\mathcal{S}$  such that  $S(\gamma) = (m_1, m_2, \dots, m_n)$  if and only if  $\gamma \in \Gamma$ , where  $\mathcal{S}(\gamma)$  means that  $\mathcal{S}$  computes shared secrets from shares of the servers in  $\gamma$ .

We define  $\Gamma$ -OT<sub>n</sub><sup>1</sup> such that  $R$  can get the secret  $m_\alpha$  from the servers in an authorized set  $\gamma \in \Gamma$ , where  $\alpha$  is  $R$ 's choice. The requirements for a satisfactory  $\Gamma$ -OT<sub>n</sub><sup>1</sup> are the same as those for the threshold OT<sub>n</sub><sup>1</sup> schemes in Section 4.

We can combine our OT<sub>n</sub><sup>1</sup> scheme and a general secret sharing scheme  $\mathcal{S}$  to form a  $\Gamma$ -OT<sub>n</sub><sup>1</sup> scheme as follows.

1. Let  $S_j$  obtain a share  $m_{i,j}$  of  $m_i$  by the secret sharing scheme  $\mathcal{S}$ ,  $1 \leq i \leq n$ .
2. Let  $\gamma$  be an authorized set that  $R$  contacts its servers to obtain  $m_\alpha$ .  
When  $R$  contacts  $S_j \in \gamma$  with  $y = g^r h^\alpha$ ,  $S_j$  responds with  $c_{i,j} = (g^{k_{i,j}}, m_{i,j}(y/h^i)^{k_{i,j}})$ ,  $1 \leq i \leq n$ .
3.  $R$  computes  $m_{\alpha,j}$  for each  $S_j \in \gamma$  and applies  $S(\gamma)$  to compute  $m_\alpha$ .

The above  $\Gamma$ -OT<sub>n</sub><sup>1</sup> scheme meets the requirements. This can be proved by the same arguments for the threshold oblivious transfer schemes in Section 4. We omit them here.

# 6 Applications

Efficient string OT<sub>n</sub><sup>1</sup> schemes can improve practical efficiency of the schemes in which oblivious transfer is used. One primary application is for private information retrieval (PIR), in which the user (U) wants to query one data block from a database, but U does not want the database manager (DBM) to know which data block he is interested in [14]. The regular PIR does not restrict U to obtain only one data block of the database. We consider the symmetric PIR (SPIR), in which DBM does not want to release more than one data block [22].

Assume that the database has  $n$  data blocks  $m_i$ 's, each is in  $G_q$ . The following steps achieve SPIR. U wants to obtain  $m_\alpha$ .

1. U sends  $y = g^r h^\alpha$  to DBM;
2. DBM computes  $c_i = (g^{k_i}, m_i(y/h^i)^{k_i})$ ,  $1 \leq i \leq n$ ;
3. Now, DBM treats  $c_i$ 's as its data blocks. DBM and U perform a regular PIR protocol so that U obtains  $c_\alpha$ .
4. U computes  $m_\alpha = b/a^r$ , where  $c_\alpha = (a, b)$ .

This method transforms any single-database PIR scheme into a single-database SPIR scheme with only an extra unit of communication cost in step 1. If U's choice  $\alpha$  of the base PIR scheme in Step 3 is computationally private, the transformed SPIR scheme's user privacy is computationally secure. On the other hand, if the base PIR scheme is unconditionally secure, the user's choice of the transformed SPIR is unconditionally private.

The transformed SPIR scheme uses at most one more round than that of the base PIR scheme. The reason is that the first step may be combined with the first step of the base PIR in step 3.

**Theorem 6.1** *If there exists a single-database PIR scheme with communication complexity  $c(n)$  and round complexity  $r(n)$ , there exists an  $OT_n^1$  scheme with communication complexity  $c(n) + 1$  and round complexity  $r(n) + 1$ , but with the additional assumption of hardness of the DDH problem.*

## 7 Further Security

Naor and Pinkas [26] give a very formal definition for security of  $OT_n^1$  oblivious transfer:

1. Receiver's privacy – indistinguishability:  $S$ 's views of  $R$ 's different choices  $\alpha$  and  $\alpha'$ ,  $\alpha \neq \alpha'$ , are computationally indistinguishable.
2. Sender's privacy – compared with Ideal Model: The Ideal Model is that there is a trusted third party (TTP) that gets  $S$ 's secrets  $m_1, m_2, \dots, m_n$  and  $R$ 's choice  $\alpha$  and gives  $m_\alpha$  to  $R$ . Sender's secrecy is that for every probabilistic poly-time substitute  $R'$  for  $R$ , there is a corresponding  $R''$  in the Ideal Model such that the outputs of  $R'$  and  $R''$  are computationally indistinguishable.

The modified  $OT_n^1$  scheme, consisting of Steps 1', 2 and 3, in Section 2.2 meets both requirements.

**Theorem 7.1** *The modified  $OT_n^1$  scheme, consisting of Steps 1', 2 and 3, in Section 2.2 meets both the requirements of Receiver's privacy and Sender's privacy above.*

**Proof.** (Sketch) Since  $R$ 's choice is unconditionally secure, the scheme meets the requirement of Receiver's privacy.

For each probabilistic polynomial-time adversary  $R'$ , substituting for  $R$ , in the real run, we can construct a corresponding  $R''$  (in the Ideal Model) whose

output is computationally indistinguishable from that of  $R'$  as follows.  $R''$  uses  $R'$  as a *re-settable* subroutine. When  $R'$  sends  $y$  and  $\beta = \text{NI-ZKIP}(g, h, y)$  to  $S$ ,  $R''$  simulates  $R'$  to get  $\alpha$  in a re-settable way with an overwhelming probability. If  $\beta$  is not legal or the simulation fails to produce  $\alpha$ , TTP outputs  $\perp$  (*abort*). The probability of TTP outputting  $\perp$  is almost equal to that of  $S$  outputting  $\perp$ . After obtaining  $\alpha$ ,  $R''$  sends  $\alpha$  to TTP and gets  $m_\alpha$ .  $R''$  sets  $c_\alpha = (g^k, m_\alpha(y/h^\alpha)^k)$  and  $c_i = (a_i, b_i)$  for  $1 \leq i \neq \alpha \leq n$ ,  $a_i, b_i \in_R G_q$ , and outputs the simulation result of  $R'$  on  $c_1, c_2, \dots, c_n$ . The output of  $R''$  is computationally indistinguishable from that of  $R'$ . If there is a claim that  $R'$  gets information about  $m_{\alpha'}$ ,  $\alpha' \neq \alpha$ . We can use  $R'$  to solve the DDH problem by manipulating its input  $c_i$ 's, which is similar to the proof of Theorem 2.2. Therefore, the scheme meets the requirement of Sender's privacy.  $\square$

## 8 Conclusion

The current trend of research on the design of cryptographic protocols is to find provably-secure practical protocols. Our results are along this direction. We have presented a very efficient (string)  $OT_n^1$  scheme and extended it to construct threshold, access-structure and verifiable  $OT_n^k$  schemes for any  $n \geq 2$  and  $1 \leq k \leq n$ . We also present its application on private information retrieval. It is interesting to find more applications of this construction.
